DEVELOPMENT OF A TSUNAMI FORECAST MODEL FOR GARIBALDI, OREGON, USA

Edison Gica

Abstract

The National Oceanic and Atmospheric Administration has developed a tsunami forecast model for Garibaldi, Oregon, as part of an effort to provide tsunami forecasts for United States coastal communities. Development, validation, and stability testing of the tsunami forecast model has been conducted to ensure model robustness and stability. The Garibaldi, Oregon, tsunami forecast model employs the Method of Splitting Tsunami (MOST) numerical code. The model has been validated with a total of five historical events and shows good agreement between observed and modeled data. The stability and reliability was tested by simulating synthetic tsunamis from different source regions and historical events. A total of 19 synthetic mega tsunami, Mw =9.3 events; 1 Mw = 7.5; and 1 Mw = 6.2 for small wave condition were used, and the forecast model was stable for 24 hours. The Garibaldi, Oregon forecast model can generate 4 hours of tsunami wave characteristics in approximately 8.46 minutes of CPU time.

1.0 Background and Objectives

The National Oceanic and Atmospheric Administration (NOAA) Center for Tsunami Research (NCTR) at the NOAA Pacific Marine Environmental Laboratory (PMEL) has developed a tsunami forecasting capability for operational use by NOAA's two Tsunami Warning Centers located in Hawai'i and Alaska (Titov et al., 2005). The system is designed to efficiently, accurately, and quickly provide basin-wide warning of approaching tsunami waves. The system, termed Short-term Inundation Forecast of Tsunamis (SIFT), combines real-time tsunami event data with numerical models to produce estimates of tsunami wave arrival times and amplitudes at a coastal community of interest. The SIFT system integrates several key components: deep-ocean observations of tsunamis in real time, a basin-wide pre-computed propagation database of water level and flow velocities based on potential seismic unit sources, an inversion algorithm to refine the tsunami source based on deep-ocean observations during an event, and high-resolution tsunami forecast models termed forecast models.

Garibaldi, Oregon, is located on the north end of Tillamook Bay (Figure 1). The current bay and entrance to Tillamook was first noted by Sir Francis Drake in 1579, but it was not until 1788 when Captain Gray entered into the bay, which is now called Tillamook Bay. The City of Garibaldi was named after Guiseppe Garibaldi, known as the liberator and unifier of Italy (Old Mill). At present it is a small town with a population of 780 (2011, U.S. Census and City Data) covering a land area of 3.367 square kilometers. The Port of Garibaldi is the closest seaport to the seaport of Portland, Oregon and is the home to major business for the city and the U.S. Coast Guard. The marina is designed to accommodate up to 300 vessels and serves as the base for commercial fishermen and charter operations (Port of Garibaldi).

The estimated per capita income (2009) is $21,507 and estimated median household income (2009) of $36,510 (City Data). A large number of the population, 48.43%, works in the manufacturing industry, followed by retail trade with 18.64% and accommodation and food services with 17.43% of the population. Other occupations are in construction (4.12%); other service (except public administration) 2.91%; forestry, fishing, hunting, and agriculture support (2.18%); transportation and warehousing (2.18%); finance and insurance (1.69%); professional, scientific and technical services (0.97%); arts, entertainment and recreation (0.97%); and health care and social assistance (0.48%) (CLR Search).

This report details the development of a tsunami forecast model for Garibaldi, Oregon. Development includes construction of a digital elevation model based on available bathymetric and topographic data, model validation with historical events, and stability tests of the model with a suite of mega tsunami events the originating from subduction zones in the Pacific Ocean.

2.0 Forecast Methodology

A high-resolution inundation model was used as the basis for development of a tsunami forecast model to operationally provide an estimate of wave arrival time, wave height, and inundation at Santa Barbara, California following tsunami generation. All tsunami forecast models are run in real time while a tsunami is propagating across the open ocean. The Garibaldi, Oregon, model was designed and tested to perform under stringent time constraints given that time is generally the single limiting factor in saving lives and property. The goal of this work is to maximize the length of time that the community of Santa Barbara, California has to react to a tsunami threat by providing accurate information quickly to emergency managers and other officials responsible for the community and infrastructure. The general tsunami forecast model, based on the Method of Splitting Tsunamis (MOST) model, is used in the tsunami inundation and forecasting system to provide real-time tsunami forecasts at selected coastal communities. The model runs in minutes while employing high-resolution grids constructed by the National Geophysical Data Center (NGDC). The MOST model is a suite of numerical simulation codes capable of simulating three processes of tsunami evolution: earthquake, transoceanic propagation, and inundation of dry land. The MOST model has been extensively tested against a number of laboratory experiments and benchmarks (Synolakis et al., 2008) and was successfully used for simulations of many historical tsunami events. The main objective of a forecast model is to provide an accurate, yet rapid, estimate of wave arrival time, wave height, and inundation in the minutes following a tsunami event. Titov and González (1997) describe the technical aspects of forecast model development, stability, testing, and robustness, and Tang et al. (2009) provide a detailed account of the forecast methodology.

A basin-wide database of pre-computed water elevations and flow velocities for unit sources covering worldwide subduction zones has been generated to expedite forecasts (Gica et al., 2008). As the tsunami wave propagates across the ocean and successively reaches Deep-ocean Assessment on Reporting for Tsunamis (DART®) observation sites, recorded sea level is ingested into the tsunami forecast application in near real-time and incorporated into an inversion algorithm to produce an improved estimate of the tsunami source. A linear combination of the pre-computed database is then performed based on this improved tsunami source, now reflecting the transfer of energy to the fluid body, to produce boundary conditions of water elevation and flow velocities to initiate the forecast model computation.

Accurate forecasting of the tsunami impact on a coastal community largely relies on the accuracies of bathymetry and topography and the numerical computation. The high spatial and 4 temporal grid resolution necessary for modeling accuracy poses a challenge in the run-time requirement for real-time forecasts. Each forecast model consists of three telescoped grids with increasing spatial resolution in the finest grid, and temporal resolution for simulation of wave inundation onto dry land. The forecast model utilizes the most recent bathymetry and topography available to reproduce the correct wave dynamics during the inundation computation. Forecast models, including the Santa Barbara, California model, are constructed for at-risk populous coastal communities in the Pacific and Atlantic Oceans. Previous and present development of forecast models in the Pacific (Titov et al., 2005; Titov, 2009; Tang et al., 2009; Wei et al., 2008) have validated the accuracy and efficiency of each forecast model currently implemented in the real-time tsunami forecast system. Models are tested when the opportunity arises and are used for scientific research. Tang et al. (2009) provide forecast methodology details.

3.0 Model Development

The general methodology for modeling at-risk coastal communities is to develop a set of three nested grids, referred to as A, B, and C-grids, each of which becomes successively finer in resolution as they telescope into the population and economic center of the community of interest. The offshore area is covered by the largest and lowest resolution A-grid, while the near-shore details are resolved within the finest scale C-grid, to the point that tide gauge observations recorded during historical tsunamis are resolved within expected accuracy limits. The procedure is to begin development with large spatial extent merged bathymetric and topographic grids at high resolution, and then optimize these grids by sub sampling to coarsen the resolution and reduce the overall grid dimensions to achieve a 4 to 10-hour simulation of modeled tsunami waves within the required time period of 10 min of wall-clock time. The basis for these grids is a high-resolution digital elevation model constructed by the National Geophysical Data Center and NCTR using all available bathymetric, topographic, and shoreline data to reproduce the wave dynamics during the inundation computation. For each community, data are compiled from a variety of sources to produce a digital elevation model referenced to Mean High Water in the vertical and to the World Geodetic System 1984 in the horizontal (NGDC). The author considers it to be an adequate representation of the local topography/bathymetry. As new digital elevation models become available, forecast models will be updated, and report updates will be posted at http://nctr.pmel.noaa.gov/Forecast_reports/. From these digital elevation models, a set of three high-resolution, “reference” elevation grids are constructed for development of a reference model, from which an ‘optimized’ forecast model is constructed to run in an operationally specified period of time. The operationally developed model is referred to as the optimized tsunami forecast model.

The high resolution 1/3 arc-second Digital Elevation Model (DEM), developed by NGDC and NCTR for Garibaldi, Oregon, covers from 123.7^0 W to 124.5^0 W; 45.1^0 N to 45.59^0 N (Figure 2). Grid dimension extension and additional information were updated as needed and appropriate. Table 1 provides specific details of both high resolution (reference) and forecast model grids; extents and complete input parameter information for the model runs are provided in **Appendix A**.

The Garibaldi, Oregon, forecast model was first developed by Dr. Aurelio Mercado in November 2008. The report was re-written to follow a standard format established by NCTR and also to fix instabilities when additional earthquake scenarios were simulated.

3.1 Forecast Area

The town of Garibaldi, Oregon is located on the north end of Tillamook Bay and is backed up against the mountain on the north, west facing the bay entrance, south facing the bay, and east facing Miami Cove (Figure 1). The land elevation on the north end facing the mountain increases rapidly while in the populated area it is relatively flat (Figure 3). The bathymetry around Garibaldi port area is steep but has shallow patches in the 1 meter range (Figure 3). It should be noted that the DEM used is based on Mean High Water. Thus, at low tides, these shallow regions might show up as sand bars.

The tide gauge at Garibaldi is located at the end of the Coast Guard pier with coordinates 123° 55.1' W and 45° 33.2'N (Tides and Currents, 2013). It was originally established on August 11, 1866. The station has a mean range of 1.90 meters (6.24 feet) and a diurnal range of 2.53 meters (8.31 feet). The stations also records water and air temperatures and barometric pressure besides water level data. Based on the records, the mean sea level is 8.19 feet from 1960-1978 and 8.24 feet from 1983-2001, yielding a difference of 0.05 feet between the two data sets (Tides and Currents). The selected warning point for the inundation model is at 236.08106479484E, 45.55439814292N with a depth 5.85 meters (Figure 4).

3.2 Historical Events and Data

There are no historical records of inundation for the city of Garibaldi. National Geophysical Data Center (NGDC, 2013) however does have tide gauge data of maximum wave height for a few events, and NOAA Center for Tsunami Research also obtained digitized tide gauge time series for some events. NGDC's database has records for the Samoa 2009, Honshu 2011, and 2012 Haida Gwaii events. Digitized tide gauge data obtained by NCTR are for 2006 Tonga, 2006 Kuril Islands, 2009 Samoa, 2010 Chile, and 2011 Honshu events. Validation of the Garibaldi, Oregon, forecast model will be done with the digitized tide gauge data.

One other historical event that will be tested with the Garibaldi forecast model is the paleotsunami Cascadia event of 1700. Again, there are no historical records of this earthquake occurring along the Cascadia subduction zone, but there is coastal evidence along the Pacific Northwest coast due to co-seismic subsidence and tsunami inundation. Witter et al. (2011) used different Cascadia rupture scenarios in their study. The rupture scenario used in this study is source L1. Table 2 lists the source parameters for L1.

3.3 Model Setup

The high resolution DEM for Garibaldi, Oregon, was developed by NGDC (Taylor et al., 2007) with a grid resolution of 1/3 arc-seconds and coverage from 123.7000W to 124.5000W and 45.0990N to 45.94900N (Figure 2). The deepest water depth covered by the NGDC domain is 464.4 meters and the highest topography elevation is 969.9 meters. The DEM for the high resolution reference inundation model and the forecast model was extracted directly from the DEM developed by NGDC. Both high resolution reference inundation model and forecast model consist of three nested grid where the outer most grid (Grid A) covers the deep ocean region, so as to capture the tsunami characteristics as it propagates in the deep ocean, while the inner most grid (Grid C) covers the shallower waters to capture the tsunami wave transformations.

Details of the nested grid (Grids A, B, and C) for the high resolution reference inundation model and forecast model including the modeling parameters used are shown in Table 1. The plots of the nested grids are shown in Figures 5 and 6 for the forecast model and reference model, respectively. Instabilities in the grid can occur due to the existence of extreme shallow regions or steep slopes. These are stabilized by doing modifications on the DEM, either by correcting the specific point manually or smoothing a cluster of nodes if the single node causing the instability is not located.

The forecast model is an optimized version of the high resolution reference inundation model which is used for tsunami forecast during an event. It is designed so that it can quickly provide 4 hours of simulated tsunami wave characteristics which includes time series at the tide gauge. For Garibaldi, Oregon, the forecast model can simulate the 4 hours of tsunami wave characteristics in approximately 8.46 minutes (Table 1). The high resolution reference inundation model, on the other hand, take about 14.7 hours to complete a simulated run of 4 hours. The forecast model was not only designed to provide a quick forecast, but was also validated with historical events to check for accuracy. The high resolution reference inundation grid was also validated with the same historical events. Table 3 lists the historical events that were used to check the accuracy of both reference inundation model and forecast model, while Table 4 lists historical events used to test the stability and reliability of the both the forecast and reference models without tide gauge comparison. Table 4 lists historical events that do not have any tide gauge data or are not digitized. Figure 7 plots the location of these events in relation to the location of Garibaldi, Oregon.

Synthetic scenarios were also run to test the stability and reliability of the forecast model. The synthetic scenarios, using earthquake magnitudes (Mw) of 9.3, 7.5, and 6.2, are listed in Tables 5 and 6 with Figure 8 showing their locations. As for the Cascadia scenario, the location of Garibaldi with respect to the initial displacement based on source L1 (Witter et al., 2011) is shown in Figure 9.

4. Results and Discussions

The development of the reference and forecast model grids requires that it be validated with historical events and be tested for stability and reliability with synthetic scenarios. A total of 19 Mw=9.3, one Mw = 7.5, and one Mw = 6.2 synthetic scenarios were tested. Validation with historical data is required to determine how well the model predicts the tsunami wave characteristics of actual events. The synthetic scenarios test whether both reference and forecast model grids will produce a stable simulation and locate possible instabilities in the developed grids. The synthetic mega-event scenarios can also be used as a preliminary risk analysis to determine which tsunami source region poses a threat to Garibaldi, Oregon. The tsunami time series at the selected tide gauge and maximum/minimum tsunami wave amplitude distribution are also compared between the reference and forecast model grids. This is to check whether the tsunami wave characteristics of the lower-resolution forecast model will not significantly deviate from the reference model grid. Part of scenario tests includes a Cascadia source developed by Witter et al. (2011).

4.1 Model Validation

The development of the DEM for the high resolution reference inundation model and forecast model requires that it be validated to determine the accuracy of the simulated tsunami characteristics as hits the coastal areas of Garibaldi, Oregon. The validation was done by comparing modeling results with recorded tide gauge data of historical events. Table 3 provides a list of the historical events used for the validation. It also contains details of which propagation unit sources (Gica et al., 2008) were used for a specific event and the scaling factors applied. During an actual event, an inversion process (Percival et al., 2011) ingests recorded DART® data and selects the corresponding propagation unit sources and the scaling factor for each unit source. The scaling factors and propagation unit sources selected are based on inversion process obtain either during the actual event from recorded DART® data. These are the historical events where NCTR has tide gauge data. The results of the comparison are discussed in Section 4.3. Although tide gauge data were not available for other historical events (Table 4), simulations were conducted to determine their effect on Garibaldi, Oregon.

4.2 Model Stability and Reliability

The development of the forecast model requires that the model provides a reliable forecast and should be stable enough to simulate several hours of the tsunami event. Part of the reliability and stability tests were done by comparing with historical data as discussed in

Section 4.1. The other set of reliability and stability tests was conducted by simulating synthetic events emanating from different regions and using different earthquake magnitudes (Mw= 9.3, 7.5, and 6.2). Since each tsunami event is unique, tests using different earthquake magnitudes and source location will indicate if the model grid developed will generate instabilities that need to be corrected. This set of tests is not exhaustive. However, representative cases from select sources should be sufficient. The 19 artificial mega-tsunamis (Mw=9.3) were generated by linearly combining twenty unit sources from the propagation database developed at NCTR (Gica et al., 2008) with a slip value of twenty five meters for each unit source. The single case Mw=7.5 uses one unit source with a slip of one meter, while the single case Mw=6.2 is to test the model for a small wave condition. Tests were conducted for a total of 12 hours simulation. The list of sources used are indicated in Table 5 for the artificial mega tsunamis and Table 6 for Mw=7.5 and Mw=6.2. Table 2 lists the source parameters for the Cascadia scenario (Witter et al., 2011).

4.3 Results of Tested Events

The development of the forecast and reference grids for Garibaldi, Oregon, was tested for stability and reliability by simulating a total of fifteen historical tsunamis, nineteen synthetic mega-events with a Mw=9.3, one Mw=7.5, one Mw=6.2, and one Cascadia earthquake scenario. Based on all these simulations, instability was observed in the C-grid along the coastal areas facing the Pacific Ocean north of Tillamook Bay entrance and a few locations inside Tillamook Bay. These instabilities were very prominent and were observed for the synthetic cases ACSZ50-59ab and ACSZ56-65ab, where the earthquake source is just offshore of Garibaldi, causing deformation on both bathymetry and topography. As previously discussed, these instabilities were fixed by correcting manually or by smoothing a cluster of nodes if the single node causing the instability is not located. A relatively stable inundation grid was finally generated, but the results created modifications along the coast. This can be clearly seen in the C-grid between Figures 5 (forecast) and 6 (reference). The coastal area north of the Tillamook Bay entrance for the forecast grid (Figure 5) is clearly different from that of the reference grid (Figure 6). Although there is an obvious change in the Digital Elevation Model to obtain a relatively stable grid, the modifications does not significantly affect the results obtained for Garibaldi, as will be discussed.

A total of five tide gauge records (Table 3) from historical events were compared with simulations using the reference inundation model and forecast model. Figures 10 – 14 plot a comparison of the maximum tsunami wave amplitude distribution of the inner most grid (Grid C) and time series at the tide gauge. Overall the reference inundation model has a finer distribution of the tsunami wave pattern as compared to the forecast model. This is expected, since the forecast model uses a lower resolution (Table 1). In general, comparison with tide gauge data show relatively good results. However the modeled first wave tends to arrive a bit earlier than recorded data, and the initial tsunami wave is underestimated.

Although tide gauge data were not available, another ten historical events (Table 4) were also simulated to determine their effect on Garibaldi and as part of the stability and reliability test. The maximum tsunami wave amplitude distribution for both forecast and reference grids, as well as tsunami time series at the selected warning point, are plotted in Figures 15 to 24. Similar to the first five historical events, the reference grid has a finer distribution of the tsunami wave pattern and higher tsunami wave amplitude, as seen in the distribution of tsunami wave pattern and warning point time series. Overall, the wave patterns are similar between the forecast and reference grids.

The synthetic events (M_w = 9.3, 7.5 and 6.2) simulated for the forecast model showed that it is both stable and reliable. Similar to the historical simulations, the reference model generally produces higher tsunami amplitude when compared with the forecast model but does have similar wave frequency. Although the mega-tsunami (Mw = 9.3) tests are not exhaustive, the results can indicate which tsunami source regions would pose a threat to Garibaldi. Representative plots of the maximum tsunami wave amplitude distribution and the tsunami time series at the warning point are shown in Figures 25 to 27. Out of 19 mega-tsunami scenarios, only one case significantly inundated Garibaldi. This is scenario ACSZ50-59, which is located offshore of Garibaldi (see Figure 8). The area that is inundated is in the Port of Garibaldi; the town itself is not (Figure 27). Similarly, the single Cascadia Scenario, which is also a near-field source (Figure 9) inundates only the Port of Garibaldi (Figure 28) and not the town of Garibaldi. Plots of the tsunami time series at the warning point for all 19 mega-tsunami scenarios are shown in Figure 29 while Table 7 lists the extent of inundation.

One issue that should be noted for these near-field sources is that the impact on the town of Garibaldi is a combination of tsunami inundation and co-seismic deformation. Due to the close proximity of Garibaldi to the earthquake sources, both land and water elevation will be affected by the earth's displacement due to the quake. The tsunami impact on the town is short-term. However the topographic and bathymetric displacement due to co-seismic deformation could possibly last a couple a decades. The amount of co-seismic deformation would entirely depend on the magnitude and size of the earthquake. Figure 30 plots the displacement of both topography and bathymetry based on the Cascadia scenario simulated.

Based on all the historical, synthetic, and Cascadia scenarios tested, one thing is evident: the sudden narrowing of Tillamook Bay entrance blocks the tsunami energy from propagating further into the bay and striking the town of Garibaldi. Only the near-field mega-events (ACSZ56-65 and Cascadia scenario) manage to inundate Garibaldi, Oregon. Even then, a significant amount of the tsunami energy was reduced in the narrow entrance before entering Tillamook Bay (Figures 25 to 27).

5. Summary and Conclusions

A reference model and forecast model has been prepared for Garibaldi, Oregon. During the development, instabilities occurred due to co-seismic deformation of near-field sources. These locations were corrected manually, or smoothing a cluster of nodes if the single node causing the instability is not located. Although there were corrections made to the DEM, both models were found to be reliable and, in general, showed good agreement with five historical tide gauge data and between the forecast and reference models.

The stability tests showed that the reference model is stable for 12 hours, and forecast model is stable for a 24 hour simulation for synthetic sources with different earthquake magnitudes (Mw = 9.3, 7.5, and 6.2) from different source regions. A total of nineteen Mw =9.3, one Mw =7.5, one Mw=6.2, and one Cascadia scenario were simulated. The mega-tsunami events not only check the stability of the optimized forecast model; it can also provide information on which source regions pose the greatest tsunami threat to Garibaldi, Oregon. From the tests conducted, it indicated that near-field tsunami sources (along the US West Coast) generate inundation on Garibaldi and also generate long term co-seismic deformation. Also, the test indicated that the natural narrowing of the Tillamook Bay entrance significantly reduces the tsunami energy entering the Bay.

Since the main objective of developing the Garibaldi, Oregon, forecast model is for tsunami forecast, the DEM has been optimized to simulate 4 hours of tsunami wave characteristics in approximately 8.46 minutes. As presented in this report, the Garibaldi, Oregon, forecast model should be able to provide a reliable forecast during an event and is stable for a 24-hour simulation.

Appendix C. Forecast Model tests in SIFT system.

The development of the forecast models requires that it can provide a reliable and stable for several hours of simulation. This is accomplished by testing the forecast model with a set of synthetic tsunami events covering a range of tsunami source locations and magnitudes. Testing is also done with selected historical tsunami events when available.

The purpose of testing the forecast model testing is three-fold. The first objective is to assure that the results obtained with NOAA's tsunami forecast system, which has been released to the Tsunami Warning Centers for operational use, are similar to those obtained by the researcher during the development of the forecast model. The second objective is to test the forecast model for consistency, accuracy, time efficiency, and quality of results over a range of possible tsunami locations and magnitudes. The third objective is to identify bugs and issues in need of resolution by the researcher who developed the forecast Model by the forecast software development team before the next version release to NOAA's two Tsunami Warning Centers.

Local hardware and software applications, and tools familiar to the researcher(s), are used to run the Method of Splitting Tsunamis (MOST) model during the forecast model development. The test results presented in this section lend confidence that the model performs as developed and produces the same results when initiated within the forecast application in an operational setting as those produced by the researcher during the forecast model development. The test results assure those who rely on the Garibaldi, Oregon tsunami forecast model that consistent results are produced irrespective of system.

C.1 Testing Procedure

The general procedure for forecast model testing is to run a set of synthetic tsunami scenarios and a selected set of historical tsunami events through the forecast system application and compare the results with those obtained by the researcher during the forecast model development as presented in the Tsunami Forecast Model Report. Specific steps taken to test the model include:

1. Identification of testing scenarios, including the standard set of synthetic events, appropriate historical events, and customized synthetic scenarios that may have been used by the researcher(s) in developing the forecast model.
2. Creation of new events to represent customized synthetic scenarios used by the researcher(s) in developing the forecast model, if any.
3. Submission of test model runs with the forecast system, and export of the results from A, B, and C grids, along with time series.
4. Recording applicable metadata, including the specific version of the forecast system used for testing.
5. Examination of forecast model results for instabilities in both time series and plot results.
6. Comparison of forecast model results obtained through the forecast system with those obtained during the forecast model development.
7. Summarization of results with specific mention of quality, consistency, and time efficiency.

8. Reporting of issues identified to modeler and forecast software development team.
9. Retesting the forecast models in the forecast system when reported issues have been address or explained.

Simulation of the Synthetic model were tested on a DELL PowerEdge R510 computer equipped with two Xeon E5670 processors at 2.93 GHz, each with 12 MBytes of cache and 32GB memory. The processors are hex core and support hyper-threading, resulting in the computer performing as a 24 processor core machine. Additionally, the testing computer supports 10 Gigabit Ethernet for fast network connections. This computer configuration is similar or the same as the configurations of the computers installed at the Tsunami Warning Centers so the compute times should only vary slightly

C.2 Results

The Garibaldi, Oregon forecast model was tested with NOAA's tsunami forecast system version 3.2.

The Garibaldi forecast model was tested with four synthetic scenarios and one historical tsunami event. Test results from the forecast system and comparisons with the results obtained during the forecast model development are shown numerically in Table 1 and graphically in Figures 1 to 5. The results show that the forecast model is stable and robust, with consistent and high quality results across geographically distributed tsunami sources and mega-event tsunami magnitudes. The model run time (wall clock time) was under 11.7 minutes for 6 hours of simulation time, and under 7.8 minutes for 4 hours. This run time is within the 10 minute run time for 4 hours of simulation time and satisfies time efficiency requirements.

Four synthetic events were run on the Garibaldi forecast model. The modeled scenarios were stable for all cases tested, with no instabilities or ringing. Amplitudes greater than 100 centimeters (cm) were recorded for two of the four test cases. The largest modeled amplitude was 323 cm and originated in the Aleutian-Alaska-Cascadia (ACSZ 56-65) source and was approximately 200 cm less than the result obtained during development. This discrepancy occurred because the tsunami forecast system does not take into account co-seismic deformation of the forecast model grids for near-field sources whereby during the development co-seismic deformation is taken into account. This is currently being addressed in the tsunami forecast system. The smallest signal of 10 cm was recorded at the Central and South America (CSSZ 91-100) source and was approximately 13 cm less than the result obtained during development. This discrepancy was found because the synthetic scenarios were run for a longer duration during development and a higher maximum was recorded at a time beyond the scope of the forecast system output. Direct comparisons of output from the forecast tool with results of the Kamchatka-Yap-Mariana-Izu-Bonin (KISZ 22-31), the East Philippines (EPSZ 30-39) and the Tohoku 2011 historical event, demonstrated that the wave patterns were nearly identical in shape, pattern and amplitude.

Table C. 1. Table of maximum and minimum amplitudes (cm) at the Garibaldi, Oregon warning point for synthetic and historical events tested using SIFT 3.2 and obtained during development.

Scenario Name	Source Zone	Tsunami Source	α [m]	SIFT Max (cm)	Development Max (cm)	SIFT Min (cm)	Development Min (cm)
Mega-tsunami Scenarios							
KISZ 22-31	Kamchatka-Yap-Mariana-Izu-Bonin	A22-A31, B22-B31	25	101.5	99.09	-30.9	-28.12
ACSZ 56-65	Aleutian-Alaska-Cascadia	A56-A65, B56-B65	25	323.0	536.95	-159.5	-160.18
CSSZ 91-100	Central and South America	A91-A100, B91-B100	25	9.5	22.42	-7.0	-11.19
NTSZ 30-39	New Zealand-Kermadec-Tonga	A30-A39, B30-B39	25	58.5	58.49	-23.2	-23.21
Historical Events							
Tohoku 2011	Kamchatka-Yap-Mariana-Izu-Bonin	See Table 2		36.4	36.4	-16.1	-16.1
