PMEL Tsunami Forecast Series: Vol. x
A Tsunami Forecast Model for Yakutat, Alaska

Liujuan Tang and Jean C. Newman

Abstract

This study describes the development, validation, and testing of a tsunami forecast model for Yakutat, Alaska. Based on the Method of Splitting Tsunamis (MOST) model, the forecast model is capable of simulating four hours of tsunami wave dynamics at a resolution of 60 m in minutes of computational time. A reference inundation model of higher resolution of 8/15" (8-16 m) was also developed in parallel, to provide modeling references for the forecast model. Both models were tested for seventeen past tsunamis and a set of twenty simulated magnitude-9.3 tsunamis. The good agreement between the model computations and observations, along with the numerical consistency between the model results for the maximum amplitude and velocity, provide a quantitative validation and reliable robustness and stability testing of the forecast model.

Based on the 37 scenarios, the error/uncertainty in η_{max} at the Yakutat gage computed by the forecast model is within 35% when $\eta_{max} > 1$m. When $\eta_{max} < 1$m, the error/discrepancy is within 11 cm except the 1960 Chile and No. 15 M_w 9.3 New Guinea tsunami. The forecast model shows good accuracy/consistency for tested local tsunamis.

Wavelet analyses were performed for the 37 scenarios to explore peak resonant periods, T_P, at the Yakutat tide gage. The site shows broad resonant periods from 11 minutes to 3 hours. The most commonly seen peak periods are 11, 50, and 160 min.

The modeled inundation limits and currents agree reasonably well between the forecast and reference models. Local mega-tsunamis from Alaska and Yakutak subduction zones can cause several inundation at the site. The results also highlight maximum waves can arrive 12 h after the first wave for far field tsunami. It would require longer warning duration during such events.

The simulated magnitude-9.3 tsunamis show an impressive local variability of tsunami amplitudes at Yakutat, and indicate the complexity of forecasting tsunami amplitudes at a coastal location. It is essential to use high-resolution models in order to provide accuracy that is useful for coastal tsunami forecasts for practical guidance.

1 Introduction

The National Oceanic and Atmospheric Administration (NOAA) Center for Tsunami Research at NOAA's Pacific Marine Environmental Laboratory (PMEL) has developed a tsunami forecasting system for operational use by NOAA's two Tsunami Warning Centers located in Hawaii and Alaska (Titov *et al.*, 2005; Titov, 2009). The forecast system combines real-time deep-ocean tsunami measurements from tsunameters (Deep-ocean Assessment and Reporting of Tsunami (DART)) stations (González *et al*., 2005; Meinig *et al*., 2005, Bernard *et al.*, 2006, Bernard and Titov, 2007) and the Method of Splitting Tsunami (MOST) model, a suite of finite difference numerical codes based on the nonlinear shallow water wave equations (Titov and Synolakis, 1998; Titov and González, 1997; Synolakis *et al*., 2008; *Titov et al*., 2011) to produce real-time forecasts of tsunami arrival time, heights, periods and inundation. To achieve accurate and detailed forecast of tsunami impact for specific sites, high-resolution tsunami forecast models are under development for United States coastal communities at risk (Tang *et al.*, 2008[a]; 2009; 2010; Arcas and Uslu, 2010; Righi and Arcas, 2010; Uslu *et al*. 2010; Wei and Arcas, 2010). The resolution of these models has to be high enough to resolve the dynamics of a tsunami inside a particular harbor, including influences of major harbor structures such as breakwaters. These models have been integrated as crucial components into the forecast system.

Presently, as shown in Figure 1, a system of 55 tsunameter stations, are deployed in the Pacific, Atlantic, Indian Oceans, Caribbean Sea, the Gulf of Mexico and South China Sea (40 U.S.-, 8 Australian-, 1 Chilean-, 1 China-, 2 Indian-, 1 Indonesian-, 1 Thailand- and 1 Russian-owned) [*Spillane et al*., 2008]. The pre-computed propagation models currently have 1,725 scenarios covering the major tsunami-genetic subduction zones in the oceans (Table 1). High-resolution forecast inundation models are now set up for 75 U.S. coastal communities (e.g. Figs. 1 and 2). The fully implemented system will use real-time data from the tsunameter network to provide high-resolution tsunami forecasts for at least 75 communities in the U.S. by 2013, with additional models envisioned later for smaller communities. Since its first testing in the 17 November 2003 Rat Island tsunami, the forecast system has produced experimental real-time forecasts for more than 20 tsunamis in the Pacific and Indian oceans (Titov *et al*., 2005; Wei *et al*., 2008; Titov, 2009; Titov and Tang, 2011; Tang *et al*., 2012; http://nctr.pmel.noaa.gov/database_devel.html; Table 2). The forecast method has also been tested with data from nine additional events that produced deep-ocean tsunameter data and near-field tsunamis (http://nctr.pmel.noaa.gov/database_devel.html; Titov *et a*l., 2005; Tang *et al*., 2008b; Wei *et al*., 2012).

The report describes the development, testing and applications of the Yakutat forecast model. The objective in developing this model is to provide NOAA's Tsunami Warning Centers the ability to assess danger posed to Yakutat following tsunami generation in the Pacific Ocean Basin with a goal to provide accurate and timely forecasts to enable the community to respond appropriately. Dr. David Burwell developed the first version of a Yakutat forecast model in 2007. It was updated in 2008 and had been working in the tsunami forecast system until January, 2013. As new bathymetric/topographic and tsunami data came

in and the model development technique progressed further, the model had been updated and re-tested in January 2013.A secondary objective of the report is to explore the potential tsunami impact from earthquakes at major subduction zones in Pacific to the city by using the developed forecast model. Wavelet analysis was applied to investigate the local responses to tsunami waves.

The report is organized as follows. Section 2 briefly introduces NOAA's tsunami forecast methodology. Section 3 describes the model development. Section 4 presents the results and discussion, which includes model validation, verification, and testing for past and simulated tsunamis. A summary and conclusion are provided in section 5.

2 Forecast Method

NOAA's real-time tsunami forecasting scheme is a process that comprises two steps: (1) construction of a propagation scenario via inversion of deep ocean tsunameter measurements with pre-computed tsunami source functions; and (2) coastal predictions by running high-resolution forecast models in real time (Titov *et al*. 1999; 2005; Titov 2009; Tang *et al*., 2009, Tang *et al*., 2012). The tsunameter-constrained tsunami source, the corresponding offshore scenario from the tsunami source function database, and high-resolution forecast models cover the entire evolution of earthquake-generated tsunamis, generation, propagation and coastal inundation, providing a complete tsunami forecast capability.

2.1 Construction of a Propagation Scenario Based on Deep-Ocean Tsunameter Measurements and Pre-Computed Tsunami Source Functions

Several real-time data sources, including seismic data, coastal tide gage and deep-ocean data have been used for tsunami warning and forecasting (Satake *et al*., 2008; Whitmore, 2003; Titov, 2009). NOAA's strategy for the real-time forecasting is to use deep-ocean measurements at tsunameter stations as the primary data source due to several key features. (1) tsunameters provide a direct measure of tsunami waves, unlike seismic data, which are an indirect measure of tsunamis. (2) The deep ocean tsunami measurements are in general the earliest tsunami information available, since tsunamis propagate much faster in deep ocean than in shallow coastal area where coastal tide gages are located. (3) Compared to coastal tide gages, tsunameter data with a high signal to noise ratio can be obtained without interference from harbor and local shelf effects. (4) Wave dynamics of tsunami propagation in deep ocean is assumed to be linear (Kânoğlu and Synolakis, 2006; Liu, 2009). This linear process allows application of efficient inversion schemes.

Time series of tsunami observations in deep-ocean can be decomposed into a linear combination of a set of tsunami source functions in the time domain by a linear Least Squares method (Percival *et al*., 2011). We call coefficients obtained through this inversion process *tsunami source coefficients*. During real-time tsunami forecasting, seismic waves propagate much faster than tsunami waves so the initial seismic magnitude can be estimated before the tsunameter data are available. Since time is of the essence, the initial tsunami

forecast is based on the seismic magnitude only. The tsunameter inverted source will update the forecast when it is available.

Titov *et al*. (1999; 2001) conducted sensitivity studies on far-field deep-water tsunamis of different parameters of an elastic deformation model described in Gusiakov (1978) and Okada (1985). The results showed source magnitude and location essentially define far-field tsunami signals for a wide range of subduction zone earthquakes. Other parameters have a secondary influence and can be pre-defined during the forecast. Based on these results, tsunami source function databases for Pacific, Atlantic, and Indian Oceans have been built using pre-defined source parameters, length = 100 km, width = 50 km, slip = 1 m, rake = 90 or -90 and rigidity = 4.5 x 10^{10} N/m^2. Other parameters are location-specific; details of the databases are described in Gica *et al*. (2008). Each tsunami source function is equivalent to a tsunami from a typical magnitude-7.5 earthquake with defined source parameters. Figure 1 shows the locations of tsunami source functions. Figure 2 shows the maximum amplitudes offshore Yakutat from the tsunami source functions.

The tsunami source functions in the database are computed with a time step of 10 seconds and a spatial resolution of 4-arc-minute (approximately 7.4 km along the N-S direction). The outputs, offshore wave height and depth-average velocities of the entire domain, are then compressed and saved every 1 minute in time and 16-arc-minute in space (Tolkova, 2007). The current propagation scenarios do not include inundation and a vertical wall is placed at 20 m water depth (Gica *et al*., 2008). The friction term is set to zero.

When tsunami waves propagate into shallow water, where under the steady-state assumption, there are not any energy losses or inputs, the decrease in transport speed must be compensated by an increase in energy density in order to maintain a constant energy flux. The low spatial resolution and simplified boundary conditions of the propagation model result in inaccurate in near-shore dynamics. As a consequence, the numerical dissipation (due to the low spatial resolution) will cause energy decay in the propagation modeling (Tang *et al*., 2012). Based on consideration of energy conservation, we have developed high-resolution, site-specific inundation forecast models built on the MOST model to simulate the near shore wave dynamics.

Energy released from an earthquake and then how portions of the earthquake energy are transferred into water column are complex dynamic processes at the stage of tsunami generation. However, the goal of tsunameter inversion is not to quantify the quantities such as energy at the initial stage of tsunami generation. Instead, we try to quantify the amount of wave energy that propagates outside the source area in the form of surface long gravity waves, which can be well measured by the tsunameter stations. It is also the propagated energy that results in the coastal impacts. Our estimates of the tsunami source (the propagation scenario) focus on the characteristics of tsunami propagation which are directly constrained by the deep ocean tsunami data. Regardless of the details of earthquake processes for tsunami generation at the initial stage, the inversion can ensure the propagation scenario gives the best approximation to the tsunami measurements, and therefore, the best estimation of the total energy transferred to the tsunami waves. The database can provide offshore forecasts of tsunami amplitudes and all other wave parameters immediately once the inversion is complete. The tsunami source, which combines real-time tsunami measurements

with tsunami source functions, provides an accurate offshore tsunami scenario without additional time-consuming model runs.

2.2 Coastal Predictions by Running High-Resolution Forecast Models in Real-Time.

High-resolution forecast models are designed for the final stage of the evolution of tsunami waves: coastal runup and inundation. Once the tsunameter-constrained tsunami source is obtained (as a linear combination of tsunami source functions), the pre-computed time series of offshore wave height and depth-averaged velocity from the model propagation scenario are applied as the dynamic boundary conditions for the forecast models. This saves the simulation time of basin-wide tsunami propagation. Tsunami inundation and nearshore currents are highly nonlinear processes, therefore a linear combination would not provide accurate solutions. A high-resolution model is also required to resolve shorter tsunami wavelengths nearshore with accurate bathymetric/topographic data. The forecast models are constructed with the Method of Splitting Tsunami (MOST) model, a finite difference tsunami inundation model based on nonlinear shallow-water wave equations (Titov and Synolakis, 1998; Titov and González, 1997; Synolakis *et al*., 2008; *Titov et al*., 2011). Each forecast model contains three telescoping computational grids with increasing resolution, covering regional, intermediate and near shore areas. Run-up and inundation are computed at the coastline. The highest resolution grid includes the population center and coastal water level stations for forecast verification. The grids are derived from the best available bathymetric/topographic data at the time of development, and will be updated as new survey data become available.

The forecast models are optimized for speed and accuracy. By reducing the computational areas and grid resolutions, each model is optimized to provide 4-hour event forecasting results in 10 minutes of computational time using one single processor, while still providing good accuracy for forecasting. To ensure forecast accuracy at every step of the process, the model outputs are validated with historical tsunami records and compared to numerical results from a reference inundation model with higher resolutions and larger computational domains. In order to provide warning guidance for long duration during a tsunami event, each forecast model has been tested to output up to 24-hour simulation since tsunami generation.

3 Model Development

3.1 Forecast area and tsunami data

Yakutat Bay is a 29-km-wide bay open to the Gulf of Alaska. In outer Yakutat Bay the great shoal at the entrance is moraine, which is about 3-4km wide with shallowest part less than 50m water depth. The moraine rises 100m above the bottom of the inner bay and sloping steeply seaward on the Pacific side (Tarr and Martin, 1914). Yakutat Bay offers a rare protected harbor on the otherwise rugged and storm tossed coast between Prince William Sound and the protected inside waters of the Slexamder Archipelago (http://northwestexplorerblog.blogspot.com/2012/07/yakutat-bay-2012.html).

Located at the end of Monti Bay at the mouth of Yakutat Bay, Yakutat is a small fishing town surrounded by a small archipelago of sheltering islands. Doggie Island, Khantaak Island and several smaller islands form natural breakwaters between Yakutat Harbor and Yakutat Bay to the west (Fig. 3). Figure 4 show the charts of Yakutat and Yakutat Harbor. As of the census of 2010, there were 662 people, 502 households, and 201 families residing in the town. The population density was 2.5 per square km (6.4/mi2). The area is known historically for fishing, mining, lumber, and fur trades, and more recently for tourism.

A Nation Ocean Service water level station in Yakutat Harbor was established on April 24, 1940. The present installation was on July 3, 1990 (http://tidesandcurrents.noaa.gov/). At the water level sensor, the mean tidal range (MN) is 2.382 m, mean sea level (MSL) is 2.159 m, and mean high water level (MHW) is 3.357 m. The mean high water is used as the reference level for the forecast model to provide a worst case for inundation forecast.

Yakutat has a long history of destructive local and far-field tsunamis by earthquakes and/or local landslides. The NGDC historical tsunami database shows 25 past tsunamis in the study area during the period of 1845-2013. A 9.0 m maximum water height was reported at Yakutat for the September 10, 1899 Yakutat Bay tsunami caused by a local, magnitude-8.2 earthquake. Six days earlier on September 4, 1899, a magnitude 8.2 earthquake at Cape Yakatage produced a 3.1m run-up at Yakutat.

On July 10, 1958, the magnitude-8.3 SE. Alaska earthquake and landslides generated the second largest run-up of 6.1m in the Khantaak Island, Yakutat Bay. The 1964 Alaska tsunami produced a 1.5m maximum wave at Yakutat tide gage.

The maximums for the events during the period of 1975-2013 range from 0.03 to 0.43m. Time series of tsunami amplitudes are available for 13 events (1946-2012) for Yakutat tide gage from NOS/CO-OPS (http://tidesandcurrents.noaa.gov; e.g. Allen *et al*., 2008), which were included in the study (Fig. 9).

As an area that has repeatedly been affected by Pacific tsunamis, Yakutat is in need of a forecast model to aid site-specific evacuation decisions.

3.2 Bathymetry and Topography

In May of 2009, the National Geophysical Data Center (NGDC developed a set of integrated bathymetric–topographic digital elevation models (DEMs) covering the Yakutat, Alaska region (Fig. 6) for the Geophysical Institute at the University of Alaska at Fairbanks (UAF). These DEMs are nested at 8", 8/3" and 8/15", with the highest resolution grid centered on the harbor at Yakutat. The details of the DEM development can be found in Caldwell *et al*. (2011).

The DEMs were generated from diverse digital datasets in the region (sources shown in Fig. 6) and were designed to represent modern morphology. The digital data were obtained from several U.S. federal, state and local agencies, including:

- NOAA's National Ocean Service (NOS hydrographic survey)
- NOAA Electric Navigational Charts
- NGDC Multibeam swath sonar
- NGDC Tracklines
- NGDC digitized soundings
- USGS NED 2" topography
- NASA 1" space shuttle radar topography
- Canadian 0.75" Digital Elevation dataset

All dataset were shifted to the World Geodetic System 1984 (WGS84) horizontal datum and transferred to MHHW vertical datum. In the current study, the three DEM were converted to MHW based on datum from Yakutat tide station.

The grid generator at NCTR's Atlas was used to generate 36" and 120" grids for the model, covering the Pacific coast in Alaska. Data sources includes:

- National Ocean Service (NOS) Pacific Northwest 30m DEM
- NGDC 3" Coastal Relief Model

The bathymetry and topography at Yakutat used in the development of this forecast model was based on the DEMs provided by the National Geophysical Data Center for NTHMP. Although no Lidar toppgraphic/bathymetric data is available at the time of development. The author considers it to be a good representation of the local topography/bathymetry. As new digital elevation models become available, forecast models will be updated and report updates will be posted at http://nctr.pmel.noaa.gov/forecast_reports/.

3.3 Model Setup

By sub-sampling from the DEMs described in section 3.2, two sets of computational grids were derived for Yakutat, a reference inundation model and the optimized forecast model.

The reference grids consist of four levels of telescoped grids with increasing resolution (Fig. 7). The A-grid covers the coasts of Alaska in 36". The B-grid covers Yakutat Bay and Disenchant Bay in 8". Run-up and inundation simulations are computed at the coastlines in C and D-grids. A 8/3" C-grid covers the Yakutat Bay entrance and while a 8/15" resolution was chosen for the D-grid to resolve the fine shapes for the small archipelago of sheltering islands, Monti Bay and Yakutat Harbor.

To improve the computational speed for operational purpose, the forecast model needs to reduce node numbers, while still providing good modeling accuracy. The Yakutat forecast model has three levels of telescoped grids (Fig. 8). The A-grid in 120" propagates wave from the propagation database (16') to the forecast site. A 16" resolution was used for the forecast B-grid, sub-sampled from the 8" DEM. Run-up and inundation simulations are computed at the coastline in C-grid. The resolutions are 16/3 and 8/3" along the E-W and N-S directions respectively. The C-grid was subsampled from the 8/3" DEM.

Figure 8 shows the Yakutat tide gage at 220.2670 °E, 59.5480 °N and 9.0 mwater depth 9.0 m. Since the Yakutat tide gage is protected from the open coast, an additional point at the open coast at 220.1459 °E , 59.5325 °N with water depth of 5.0 m, was chosen in the study (Fig.8) .

Grid details at each level and input parameters are summarized in Table 3. A vertical wall was placed at 5m water depth for the A- and B- grids. All model runs were tested on a DELL PowerEdge R510 computer (e.g. tgrid23.pmel.noaa.gov) equipped with two Xeon E5670 processors at 2.93 Ghz, each with 12 MBytes of cache and 32GB memory. The processors are hex core and support hyperthreading, resulting in the computer performing as a 24 processor core machine. Additionally, the testing computer supports 10 Gigabit Ethernet for fast network connections. This computer configuration is similar or the same as the configurations of the computers installed at the Tsunami Warning Centers so the compute times should only vary slightly. For a 4-h event simulation, it takes 7 h for the reference model while it is only 7.83 minutes on a single processor for the forecast model.

4 Results and Discussion

Both the Yakutat reference and forecast models were tested with the seventeen past tsunamis summarized in Table 2. Since recorded historical tsunamis provide only a limited number of events, from limited locations, more comprehensive test cases of destructive tsunamis with different directionalities are needed to check the stability and robustness for the forecast model. Figure 2 shows the maximum amplitude offshore Yakutat from the propagation database. A set of eighteen simulated magnitude-9.3 tsunamis similar to Tang *et al*. (2006; 2008[a], 2010) was selected here for further examination. Each simulated earthquake involves 20 tsunami source functions (10 pairs) and a uniform 29-m coefficient. The 10 pair of tsunami source functions along the Cascadia involves the whole Cascadia subduction zone. Two additional scenarios, No. 19 Kodiak Island and No. 20 near Yakutat were chosen here as the local tsunamis to Yakutat. Both models were numerically stable for all of the tested scenarios

Figures 9 and 10 show the amplitude (η) time series at the Yakutat tide gage for the past tsunamis and simulated magnitude-9.3 tsunamis respectively. Tables 4 and 5 summarize the $\eta_{\max}$ and error. The error or uncertainty are computed as:

$$error = \frac{|\eta_{\max 2} - \eta_{obs}|}{\eta_{obs}} \times 100$$

$$uncertainty = \frac{|\eta_{\max 2} - \eta_{\max 1}|}{\eta_{\max 1}} \times 100 \quad \text{if } \eta_{obs} \text{ is not available}$$

where $\eta_{\max 1}$ and $\eta_{\max 2}$ are the maximum water surface elevation computed by the reference and forecast models respectively; η_{obs} is the observed maximum water surface elevation at the tide gage.

Based on the 37 scenarios, the error/uncertainty in $\eta_{\max}$ at the Yakutat gage computed by the forecast model is within 35% when $\eta_{\max} > 1$m (Fig. 13a). When $\eta_{\max} < 1$m, the error/discrepancy is within 11 cm except the 1960 Chile and No. 15 M_w 9.3 New Guinea tsunami.

The forecast model shows good accuracy/consistency for three tested local tsunamis, the 1964 Alaska tsunami, the No. 20 Yakutat and No. 19 Kodiak magnitude-9.3 tsunamis. The error/discrepancy is 25, 8 and 1% for $\eta_{\max}$ of 1.78, 3.87 and 9.31 m respectively.

The largest error of 0.92 m in $\eta_{\max}$ among the tested tsunami is found for the 1960 Chile tsunami, where η_{obs} =0.72 m and $\eta_{\max 2}$ =1.64m cm, 128% overestimated (Fig. 9.4). It should be noted the source for this event was taken directly from the seismic source (Kanamori and Cipar, 1974). It has not been calibrated by any water level data. It is subject to debate and adjustments.

The No. 15 magnitude-9.3 New Guinea scenario shows the second largest discrepancy of 0.59 m (Fig. 10.15). The reference model computed a maximum wave of 0.77m while the forecast model shows a 1.36 m maximum. The arrivals of the maximum are consistent for the two models, which are 10 hours after the first wave.

Wavelet analyses were performed for the 37 scenarios to explore peak resonant periods, T_P, at the Yakutat tide gage. Figures 11 and 12 show the amplitude spectrograms for the past and simulated tsunamis respectively. The site shows broad resonant periods from 11 minutes to 3 hours (Fig. 15b). The most commonly seen peak periods are 11, 50, and 160 min.

Figure 15 show interesting patterns between the error/discrepancy to the η_{max} or T_P.

(1) The forecast model produced larger η_{max} than the reference model when η_{max} >1.0m (Fig. 15a)
(2) The forecast model produced larger η_{max} than the reference model for tsunamis with long peak periods (Fig. 15 b).

Figures 14 and 15 compare tsunami amplitude time series at the open coast and the Yakutat tide gage for the past and simulated tsunamis respectively. The open coast experiences much higher amplitude waves than those within the Grays Harbor for large waves. Figure 16 shows a quadratic polynomial fit for η_{max} at these two locations.

Figure 17 and 18 show both the reference and forecast models produced similar maximum water elevation, maximum current and inundation limit in the study area for most of the tested cases. Large maximum currents can be seen in both the reference and forecast models for many of the scenarios, especially over the moraine and shallow areas.

Tsunami waves in the study area vary significantly for the 20 magnitude-9.3 scenarios. The local tsunami, No. 20 Yakutat scenarios, produces waves over 9m at the Yakutat tide gage and 11 m wave at the open coast. The inundations are significant. The No. 19 Kodiak Island, No. 6 Cascadia scenarios generate waves over 4 and 2m respectively. These results show the complexity and high nonlinearity of tsunami waves nearshore, which again demonstrate the value of high-resolution forecast model for providing accurate site-specific forecast details.

5 Summary and Conclusions

A tsunami forecast model was developed for Yakutat, Alaska. The computational grids for the Yakutat forecast model were derived from the best available bathymetric and topographic data sources. The forecast model is optimally constructed at 80m resolution, to enable a 4-hr inundation simulation within minutes of computational time using a single processor. A reference inundation model of higher resolution of 8/15" (8-16m) was also developed in parallel, to provide modeling references for the forecast model. Both models were tested for seventeen past tsunamis and a set of twenty simulated magnitude-9.3 tsunamis. Two points, one at the Yakutat tide gage inside the Yakutat Bay, and the other at the open coast, were chosen as the warning points for the site.

Based on the 37 scenarios, the error/uncertainty in η_{max} at the Yakutat gage computed by the forecast model is within 35% when $\eta_{max} > 1$m. When $\eta_{max} < 1$m, the error/discrepancy is within 11 cm except the 1960 Chile and No. 15 M_w 9.3 New Guinea tsunami.

The forecast model shows good accuracy/consistency for three tested local tsunamis, the 1964 Alaska tsunami, the No. 20 Yakutat and No. 19 Kodiak magnitude-9.3 tsunamis. The error/discrepancy is 25, 8 and 1% for η_{max} of 1.78, 3.87 and 9.31 m respectively.

Wavelet analyses were performed for the 37 scenarios to explore peak resonant periods, T_P, at the Yakutat tide gage. The site shows broad resonant periods from 11 minutes to 3 hours. The most commonly seen peak periods are 11, 50, and 160 min.

The modeled inundation limits and currents agree reasonably well between the forecast and reference models. Local mega-tsunamis from Alaska and Yakutak subduction zones can cause several inundation at the site. The results also highlight maximum waves can arrive 12 h after the first wave for far field tsunami. It would require longer warning duration during such events.

The simulated magnitude-9.3 tsunamis show an impressive local variability of tsunami amplitudes at Yakutat, and indicate the complexity of forecasting tsunami amplitudes at a coastal location. It is essential to use high-resolution models in order to provide accuracy that is useful for coastal tsunami forecasts for practical guidance. In additional to the local tsunamis from Cascadia and Canada, the study shows mega tsunamis from Kodiak, Izu, Unimak, Yakutat, Manus and East Philippines subduction zones can potentially generate large amplitude waves at the open coast. It also shows the open coast of Ocean Shores and Yakutat are under high flooding risk once inundation occurs in the area

Appendix A.

Since the initial development of the forecast model for Yakutat, Alaska, the parameters for the input file for running the forecast and reference models have been changed to reflect changes to the MOST model code. The following appendix lists the new input files for Yakutat.

A1. Reference model *.in file for Yakutat, Alaska—updated for 2013

Figures

Figure 1 (a) Overview of the tsunami Forecast System. System components include tsunameter (DART) network (triangles), pre-computed tsunami source function (unfilled black rectangles) and high-resolution forecast models (red squares). Filled color shows the offshore forecast of the computed maximum sea surface elevation in m for the March 11, 2011 tsunami. Contours indicate the travel time in hours. (b) Past tsunamis and (c) a set of twenty simulated magnitude-9.3 tsunamis tested in this study. 32

Figure 2 Maximum sea surface elevation ($\eta_{\max}$) offshore Yakutat from 1129 magnitude-7.5 earthquakes. Data were taken from NCTR's pre-computed propagation database. Heights and colors of the bars represent $\eta_{\max}$ and the first arrival at the offshore point (219.75°E, 57.7936°N; water depth = 3278 m) respectively. 1-20, twenty simulated magnitude-9.3 tsunamis. 33

Figure 3 Historical tsunamis (National Geographic Data Center's database). 34

F**igure 4** An aerial photo of Yakutat. 35

Figure 5 NOAA charts show (a) Yakutat and (b) Yakutat Harbor (NOAA Chart 16716). Soundings in fathoms at Mean Lower Low Water. Contour and summit elevation values are in feet above Mean Sea Level. 37

Figure 6 Bathymetric and topographic data source overview for the Yakutat DEM. The DEM was developed at NGDC for Yakutat NTHMP (image courtesy of Caldwell *et al*. (2011)). 38

Figure 7 The four grids for the Yakutat reference model. Resolutions are (a) 36", (b) 8", (c) 8/3" and (d) 8/15" . Red boxes are boundaries of the telescoping grids for the reference model; black dashed boxes show boundaries of the forecast model grids. 40

Figure 8 Grid setup for the Yakutat forecast model. Grid resolutions are (a) 120 ", (b) 16", and (c) 5.34 by 2.67". Red boxes, boundaries of the telescoping grids. 42

Figure 9 Observed and modeled tsunami amplitude time series for past tsunamis. Black, observations; red forecast model; green, reference model. 45

Figure 10 Modeled η time series by the Yakutat reference and forecast models for simulated magnitude-9.3 tsunamis. 47

Figure 11 (a) Modeled η time series at Yakutat tide station for the past tsunamis. (b) Wavelet–derived amplitude spectrograms for the observations. (c-e) Real part of the spectrograms. 56

Figure 12 (a) Modeled η time series at Yakutat tide gage for the 20 simulated magnitude-9.3 tsunamis. (b) Wavelet–derived amplitude spectrogram for the reference model. (c and d) Real part of the spectrograms computed by the reference and forecast models. 66

Figure 13 (a) Forecast error/uncertainty in the $\eta_{\max}$ at the Yakutat tide gage for the 38 tsunamis. (b) Uncertainty v.s. peak period. Filled markers, 18 past tsunamis; open markers, 20 simulated magnitude- 9.3 tsunamis. $\eta_{\max 1}$ and T_{p1}, maximum water elevation and peak period at the gage

from either observations or the reference model(when the observations are not available). η_{max2} and T_{p2}, maximum water surface elevation and peak period at the gage computed by the forecast model. 67

Figure 14 Time series of sea surface elevation η at the opean coast and Yakutat gage for the past tsunamis. Results are from the forecast model..... 69

Figure 15 Time series of sea surface elevation η at the open coast and Yakutat tide gage for the 20 simulated magnitude-9.3 tsunamis. Results are from the forecast model. 71

Figure 16 Comparison of the maximum water elevations at the Yakutat tide gage with those at the open coast for the 37 scenarios. η_{max} was computed by the Yakutat focast model. See Fig 13 for the list of the markers. Solid black line is a quadratic polynomial fit to the data; p0-p2, coefficients. 72

Figure 17 Maximum water elevation and current computed by the Yakutat reference and forecast models for past tsunamis..... 89

Figure 18 Maximum water elevation and current computed by the Yakutat reference and forecast models for the simulated magnitude-9.3 tsunamis..... 109

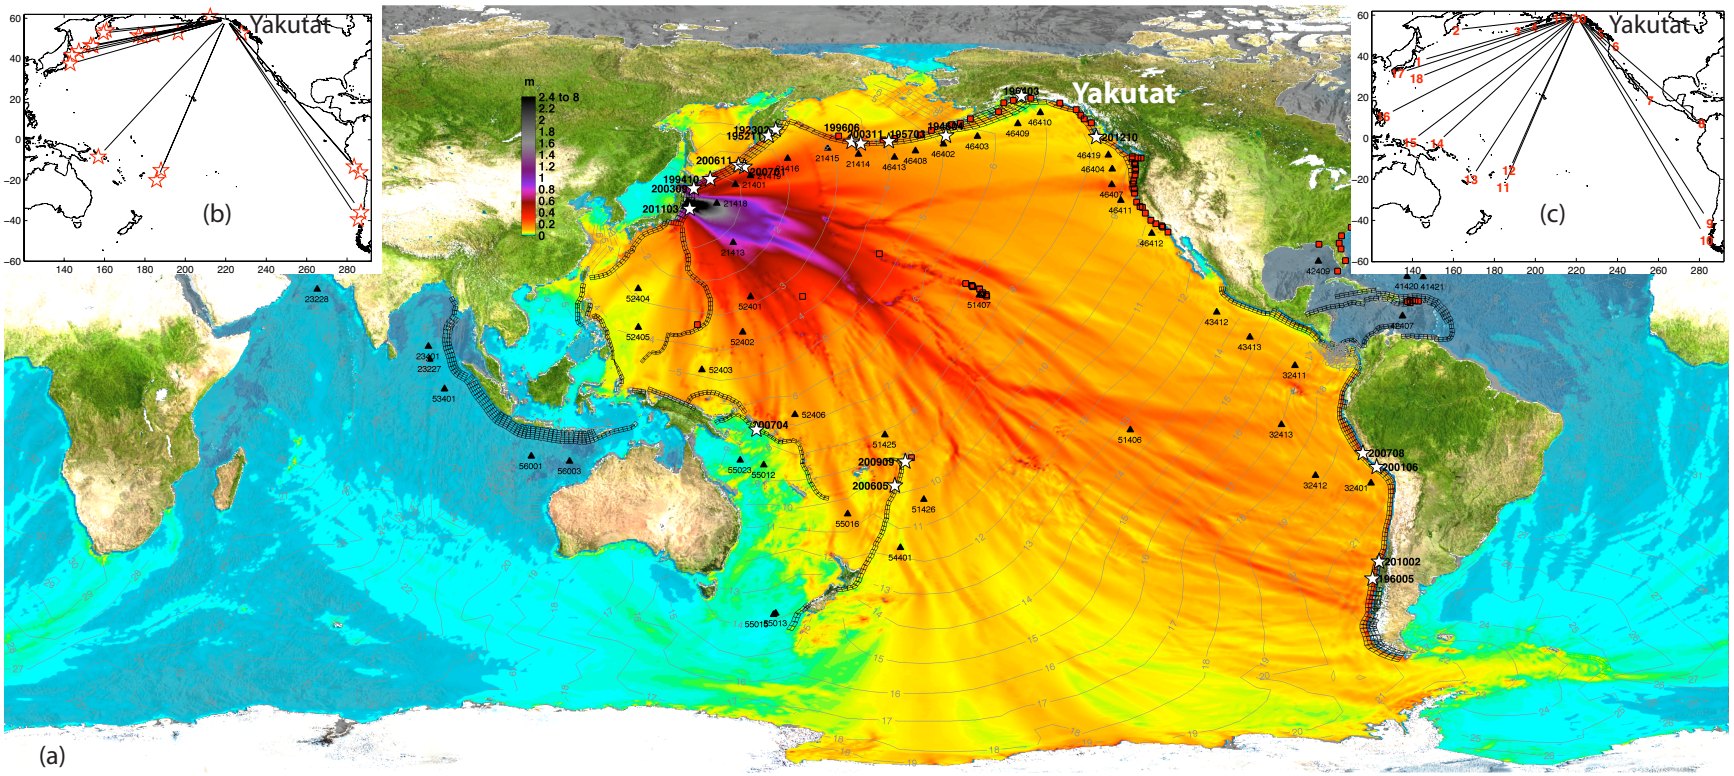

Figure 1 (a) Overview of the tsunami Forecast System. System components include tsunameter (DART) network (triangles), pre-computed tsunami source function (unfilled black rectangles) and high-resolution forecast models (red squares). Filled color shows the offshore forecast of the computed maximum sea surface elevation in m for the March 11, 2011 tsunami. Contours indicate the travel time in hours. (b) Past tsunamis and (c) a set of twenty simulated magnitude-9.3 tsunamis tested in this study.
