Abstract

Based on Method Of Splitting Tsunami (MOST) numerical model, a tsunami Forecast Model has been developed for a city of Sitka, AK, along with a reference inundation model at higher resolution and larger space coverage. Both models showed robust performance with a number of historical and synthetic events, including extreme scenarios. Simulations of historical tsunami events with the Forecast Model and with the Reference Model are in good agreement with available tsunami records at Sitka tide gage. Simulations of artificial events were conducted to test the models for stability and mutual consistence. It is expected, that the forecast model for Sitka, AK, is able to provide an accurate estimate of a wave arrival time, wave height, and inundation extend in minutes of computational time in advance of a tsunami arrival, should the tsunami happen.

1 Background and objectives

The National Oceanic and Atmospheric Administration (NOAA) Center for Tsunami, Research (NCTR) at the NOAA Pacific Marine Environmental Laboratory (PMEL) has developed a tsunami forecasting capability for operational use by NOAA's two Tsunami Warning Centers located in Hawaii and Alaska (Titov et al., 2005). The system is designed to efficiently provide basin-wide warning of approaching tsunami waves accurately and quickly. The system, termed Short-term

Inundation Forecast of Tsunamis (SIFT), combines real-time tsunami event data with numerical models to produce estimates of tsunami wave arrival times and amplitudes at a coastal community of interest. The SIFT system integrates several key components: deep-ocean observations of tsunamis in real time, a basin-wide pre-computed propagation database of water level and flow velocities based on potential seismic unit sources, an inversion algorithm to refine the tsunami source based on deep-ocean observations during an event, and high-resolution tsunami forecast models.

Sited at the base of an extinct volcano, Sitka was first observed by Europeans on the Bering expedition of 1741 where it was noted for its location and resources. Soon after initial observation, Sitka was colonized and became the capital of Russian America (Sitka, 2010-2011). Following the United States purchase of Alaska in 1867 Sitka became the capital of the Alaska territory and maintained this position until 1906 when the capital was moved to Juneau. Sitka is located on Baranof Island and is only accessible by boat and plane. Today, Sitka serves as the seat of the Borough of Sitka. The 2010 census reported 8,881 people and 3,516 households reside in the town (<http://quickfacts.census.gov/qfd/states/02/02220.html>), making it the fourth largest city by population in the state of Alaska. US Coast Guard Air Station Sitka and Rocky Gutierrez Sitka Airport are both located on Japonski Island in Sitka Sound. The Borough of Sitka is known historically for resource extraction including shing, mining, lumber. A large fishing fleet in Sitka Harbor is specialized in salmon, halibut, and sablefish. Sitka is the 6th largest port by value of seafood harvest in the United States. Recently, the economy has diversified into accommodating summer cruise ships and eco tourists. Cruise ships bring over 120,000 people to Sitka annually (Sitka, 2010-2011). Figure 1 shows satellite view to the Sitka sound.

Due to its remote location, low-lying population center, and high influx of seasonal tourists, the potential impact of a tsunami event on the economy and infrastructure of Sitka is high. To manage this risk, the Tsunami Warning Centers designated Sitka as a community that would benefit from a tsunami forecast model. In 2003, Sitka was designated a Tsunami Ready community.

The first version of a Sitka forecast model was developed by Dr. David C. Burwell in 2006. It had been working in the SIFT system until October 2012. As new tsunami data were collected and the model development technique progressed further, the model had been re-visited. This report describes the development and testing of an updated Sitka forecast model including analysis of existing tsunami records, computational grid development, numerical set-up, model validation with historical events, and further stability testing with synthetic events.

2 Forecast Methodology

The NOAA tsunami forecast system employs the Method of Splitting Tsunami (MOST) numerical model (Titov & Synolakis , 1998), which is a set of code for simulating three processes of tsunami evolution: generation by an earthquake, transoceanic propagation, and inundation of dry land at specific sites.

The forecast is supported by the database of an ocean-wide 24-hour-long simulation of a tsunami wave propagation, for numerous tsunamis generated by hypothetical unit earthquakes covering worldwide subduction zones (Gica et al., 2008). As the tsunami wave propagates across the ocean and reaches tsunameter observation sites, the forecasting system uses a data inversion technique coupled with a pre-computed tsunami generation scenarios to deduce the tsunami source in terms of the database of unit earthquakes (Percival et al., 2009). A linear combination of the pre-computed unit tsunamis is then used to determine the offshore tsunami waves and to produce synthetic boundary

conditions of water elevation and flow velocities into site-specific forecast models. The main objective of a forecast model is to provide an accurate estimate of a wave arrival time, wave height, and inundation extend at a particular location in minutes of computational time, in advance of the wave arrival. Previous and present development of forecast models in the Pacific (Titov et al., 2005; Titov, 2009; Tang et al., 2008; Wei et al., 2008) have validated the accuracy and efficiency of each forecast model currently implemented in the real-time tsunami forecast system.

3 Model Development

Each forecast model consists of three nested grids with increasing spatial resolution, referred to as A, B, and C-grids. The outer and the coarser grid A receives its boundary input of water elevation and flow velocities from the pre-computed database, and provides the boundary input of a re-fined (with respect to the database) solution into B grid, which is smaller in extent and finer in resolution. The B-grid solution, refined further, provides the boundary input into the finest and smallest of the three C grid. Within C grid, the solution is expected to be accurate enough to match the major features of a tide gauge tsunami record.

All tsunami forecast models are run in real time while a tsunami is propagating across the open ocean. Thus the computational time is the critical factor for a model development. Meeting the time constrain is achieved by manipulating with the spatial and temporal resolution of grids used in modeling, with an objective to balance computational speed with numerical accuracy.

The development of a Forecast Model is centered around "optimizing" (reducing) coverage and resolution of computational grids, to reduce the computational time as much as possible without noticeable degradation of the numerical solution, in particular, a time history at an observational point (usually, at a tide gage location). Time histories computed with optimized grids are evaluated by visual comparison with the time history obtained with a reference model comprised of larger and/or finer grids (Tang et al., 2009).

3.1 Forecast Area

Sitka is located on the lowlands along the Gulf of Alaska on Sitka Sound, on the west side of Baranof Island. Sitka Sound is a complex archipelago of low-lying pinnacles and interconnected islands. The deepest charted depth in the approaches to Sitka Sound is 105 fathoms with rapid and complex shoaling occurring to the north and east. In this region of southeast Alaska, the continental shelf extends approximately 35 miles offshore.

Sitka is facing the Fairweather - Queen Charlotte (FW-QC) transform fault system, which is the most active part of the Pacific - North America plate boundary in Southeast Alaska. The northern Fairweather fault has a slip rate of 44.62.0 mm/yr, one of the highest rates observed across any strike-slip fault in the world (Fletcher and Freymueller, 2003). Large earthquakes on the fault occurred in 1927 (Ms 7.1), August 22, 1949 (Ms 8.1), July 10, 1958 (Ms 7.9-8.2), and July 30, 1972 (Ms 7.6), the rupture areas shown in Figure 2. However, all earthquakes observed so far in the Sitka region of the fault display strike-slip mechanism (Suleimani et al., 2013), which is not efficient in generating tsunamis (though 1958 earthquake caused a rockslide which resulted in one of the largest local tsunamis ever recorded, with 530 m high surge in Lituya Bay, AK). The tectonic plate convergence exists in the southern part of QC fault which can result in more tsunamigenic subduction-type earthquakes, as the recent Ms 7.7 Haida Gwaii earthquake of October 28, 2012. ATWC historic tsunami database (http://oldwcawc.arh.noaa.gov/web_tsus/pastaor_tsunamis.htm) has tsunami data of the

1949, 1958, and 1972 events. In each of the three events, as well as in the 2012 event, tsunami wave amplitude detected at Sitka was under 10 cm.

While damaging locally-generated tsunamis have not been observed in Sitka region, which is explained by the regional tectonic regime, far-field tsunamis affected the city of Sitka and its surroundings several times in the past 100 years.

3.1.1 Sitka tide gage and historical tsunami records

The area's tide gage ($57^{\circ}3.1' \text{ N}$ and $135^{\circ}20.5' \text{ W}$) maintained by National Ocean Service (NOS) is located in a fish processing building 250 ft down the pier in the Sitka Sound Seafood Dock (see Figure 3 for the gage image and Figure 13 for the gage location). The mean range at Sitka is 7.70 feet and the diurnal range is 9.94 feet. Mean sea level is recorded at 9.81 feet. The gauge was first established in 1938 and has been in its current installation since 1989, when a digital tide gauge was installed. Prior to this, the gage data were recorded as marigrams. Model to data comparisons in this report use digitized marigrams if available (in particular, a collection of digitized historical tsunami records is hosted by ATWC at http://oldwcatwc.arh.noaa.gov/web_tsus/pastaor_tsunamis.htm), and the tsunami source estimates, produced by NCTR.

Events listed in Table 2 were recorded at Sitka tide gage and will be referred to in this report. Location of the events' epicenters is shown in Figure 17. Spaeth and Berkman (1967) report maximum recorded rise or fall (through-to-peak or peak-to-through elevation) of 2.6 ft in 1946 event, 1.5 ft in 1952, 2.6 ft in 1957, 3.0 ft in 1960, and 14.3 ft in the Great Alaskan tsunami of 1964, which is also the largest tsunami wave recorded at Sitka tide gage.

3.2 Tsunami wave dynamics, as inferred from tsunamis records

Continental shelf generally protects Sitka from ocean waves. At the same time, it can act as a waveguide or traps some wave energy. Due to the later, there is high level of background signal at the gage, composed of shelf waves and oscillations of adjacent water masses. Thus only the major trans-Pacific tsunamis or the tsunamis originated relatively close-by can leave distinct records at Sitka tide gage. Many recent tsunami recorded throughout the Pacific, such as Sep. 29, 2009 Samoa tsunami or Jan 13, 2007 Kuril tsunami, both due to Mw 8.1 earthquakes, are hard to distinguish in the background signal of the Sitka gage.

The tsunami records at Sitka listed in Table 2 are analyzed below for temporal and spectral content, with an objective to infer on tsunami wave dynamics. The power spectrum of each record was estimated as an amplitude of the Discrete Fourier Transform of a central fragment of the record auto-correlation coefficient computed for time lags from -511 min to 512 min and weighted with a raised cosine window (Hamming, 1998). This technique, suggested in (Tolkova and Power, 2011), sets the desired spectral resolution independently of the record duration, while using the entire data set. The power spectrum, or energy spectrum density of a time-series is expressed in $m^2 \cdot h$ or $cm^2 \cdot h$, with the area under the spectrum equal to the average squared value in the time series of N samples at Δt interval, or the record's variance.

The area's selectivity to wavelength/frequency, if any, shows itself in spectra of background signal (seiche). After the tidal component in the gage record was removed with Butterworth filter with 4 hour cut-off period, average power spectrum of the residual (background signal) was computed to detect normal oscillations in the area, if any. Figure 4 shows power spectrum, or energy spectral density, of the gage background signal computed with a 12-day long record of the gage in Jan. 2-13, 2012. Root-mean-square (rms) value of the signal is 1.4 cm. The spectrum is strongly dominated

by a frequency of about 0.5 cycle/hour, followed by a few lower spectral peaks at 1.3 c/h, 2.4 c/h, and higher.

Figures 5-10 show power spectra of the records of five tsunami events in 1946, 1952, 1964, 2010, and 2011, in where we can see essentially the same spectral peaks, which indicates excitation of local resonances. The lowest resonant frequency of 0.5 c/h, at depth of about 100 m, corresponds to a lowest normal mode (pumping mode) in a resonator 50 km long, which might indicate the bay coupled to the adjacent segment of the continental shelf. Determining the space extent of a normal mode requires more specific analysis (Tolkova and Power, 2011) and is beyond the scope of this work. The next spectral peak at 1.3 c/h might correspond to a pumping mode in a resonator 22 km long, which is the length of the bay itself. As the tsunami records show, the wave sets up the shelf pumping mode as it comes in. Every tsunami record starts with a wave with about 2 h period. After 1-2.5 h, higher frequencies appear in all records, except the record of the Great Alaskan tsunami of 1964. We suggest, that some of the higher peaks identify waves, which were trapped by the continental shelf and propagated along it. Those waves come 1-2.5 hours after the first arrival.

3.3 Model Setup

3.3.1 Bathymetry sources

Computational grids for the inundation tsunami models were developed using the following bathymetry/topography data:

- ETOPO1 1 arc-min grid (21601 by 10801 cells) of Earth's surface covering Pacific ocean from the top of the Antarctic to the Greenland ice sheets (Amante and Eakins, 2009), re-sampled in PMEL to 30 arc-sec.
- A grid developed in PMEL in 2005, which covers Sitka sound and adjacent ocean with a 9 sec spacing (152 m in x-direction, 278 m in y-direction). Referenced to Mean High Water.
- A 1/3-sec (5.6 m in x-direction, 10 m in y-direction) grid within the coordinate boundary 135.83 to 135.08 W and 56.78 to 57.27 N created by NGDC in FY11 for NCTR (Grothe et al., 2010). The DEM area covers the coastal region of Baranof Island centered on Sitka Harbor, and includes most of the Sitka sound. Referenced to Mean High Water.

The outermost A grid was cut from the 30-sec Pacific-wide grid. The intermediate level B grid was cut from the merged 9-sec and 1/3-sec grids. The last source grid was low-pass filtered to avoid aliasing when re-sampled to desired resolution. Finally, C-grid was cut from the 1/3-sec DEM. To ensure stability in simulations, all modeling grids were processed for SSL (Tolkova, 2013) which restricted variation of the refraction index between any two neighboring nodes to 2.1 times in A and C grids, and 1.9 in B grids.

The parameters of the reference and optimized grids are given in Table 1, and the grids' coverage is shown in Figures 11-13. Reference A and B grids were cut in a rotated spherical coordinate system which equator is aligned with the shoreline. Consequently, those grids have cells least affected by depression in latitude, and their cell size is given in seconds of Great arc. Computational (CPU) times listed in the Table and anywhere in this work were recorded with Dell PowerEdge R510 Linux machine, 2 x 2.93 GHz Xeon E5670 hex-core processors, running MOST code compiled with PGI Fortran compiler.

Run times listed in Table 1 correspond for 10-hour-long simulation after a tsunami entered A grid. Run times in individual grids are obtained with MOST v.4, without using its option to parallelize computations. The last column shows the total duration of the entire 10-hour simulation in either set of grids, depending on the MOST version.

3.3.2 Grid selection

Based on the expected tsunami dynamics in the area, the grids parameters were decided upon as follows:

- The outermost (A) grid resolution should allow for resolving coupled bay-shelf resonance and a shelf wave. Thus both reference and optimized A grids were selected with a relatively fine resolution of 20 sec and 30 sec of a great arc, respectively.
- A-grid coverage is essential for reproducing the shelf wave formation. It is expected, that during the first 1-2 h, the simulated wave train, arriving in Sitka following the deep ocean pass, would be fairly independent of A-grid coverage as long as the grid extends past the continental shelf in vicinity of the Sitka sound. However, waves arriving later following the continental shelf, would, on average, be the less intensive the less of the shelf is included into A grid.
- B grid, either reference or optimized, should encompass the Sitka sound and resolve its oscillations.
- The wave is correlated in space on a scale of the Sitka sound and is already well resolved in the B grid. Refining it further with the use of a C grid is needed to simulate the wave behavior in immediate vicinity of the shoreline and to account for inundation if any.

To assist with and to justify the grid selection, the Forecast Model development was carried out with MOST version 4, rather than with the current operational version (v.2). The version 4 performs computations in one grid at a time and saves the boundary input time-series along the perimeter of each next-level grid (Tolkova, 2013). This allows to decide on how changing parameters (coverage, resolution) of the specific grid would affect the next level solution, and to select parameters of one grid at a time. The version 4 also allows to use shoreline-oriented grids.

Figure 11 shows the extent of the outer level grids used in this model development. The larger 20-s grid serves as a reference grid. It includes a large section of the continental shelf to the northwest of Sitka, to being able to correctly simulate trapping and re-directing the wave within a large stretch of the shelf. The extent of the smaller 30-s grid, used as an optimized A grid, was selected to definitely encompass features essential for the wave transformation on the shelf in the vicinity of the Sitka sound. Reference A grid, cut in a rotated spherical coordinate system, has a coverage of $6.0^\circ \times 11.0^\circ$ of Great arc, or $667.9 \text{ km} \times 1224.5 \text{ km}$. Optimized A grid has a coverage of 2.917° (55.1417°N to 58.0584°N) $\times 2.195^\circ$ (223.3247°E to 225.5197°E), or $324.7 \text{ km} \times 134.5 \text{ km}$.

To illustrate the effect which A-grid coverage could have on the result, two tsunami scenarios were simulated, each with the use of the same B and C grids, but different A grids. Figures 14 and 15 show simulated time histories of the March 9, 1957, and the March 11, 2011 tsunamis at Sitka tide gage. Simulation was performed with the same (reference) set of B and C grids enclosed in either reference or optimized A grid. The results obtained with different A grids remain very close for about 2 h, after which time higher frequency waves arrive, higher intensity when computed with the larger grid.

Reference B grid, in a rotated coordinates, has a coverage of $0.53^\circ \times 0.5^\circ$ of Great arc, or $59.00\text{ km} \times 55.66\text{ km}$, and a resolution of 6 sec of Great arc. Optimized B grid has a coverage of 0.55° (56.75°N to 57.3°N) $\times 0.8^\circ$ (224.1°E to 224.9°E), or $61.23\text{ km} \times 48.39\text{ km}$, and a resolution of 9 sec in latitude and 16.525 sec in longitude.

A purpose of a C grid is to refine a B-grid solution and to provide an inundation forecast for a locality. Thus a B-grid solution provides the starting point from which refinements are to be made. Figure 16 displays time histories at the gage location obtained directly from the optimized B-grid, and further refined with either optimized or reference C grid. It can be seen, that B-grid solution provides a time history estimate very close to the ones refined with C grids. Time histories obtained with the reference and optimized C grids are very close as well. C grid contributed little in computing the wave form, but might be needed to account for inundation in large events. Thus the C grid extent (same for the Reference Model and the Forecast Model) was selected to include the low-lying area in the Sitka town, while the resolution was selected as commonly used: $2/3$ s for RM, and 3 s for FM. C grid extent is 0.0417° (57.0292°N to 57.0708°N) $\times 0.1149^\circ$ (224.6042°E to 224.7191°E), or $4.638\text{ km} \times 6.957\text{ km}$.

The models' parameter files are given in Appendix.

4 Results and Discussion

4.1 Model Validation with Historical Tsunami Records

Tsunami events, for which both a legitimate gage record and a reliable estimate of the tsunami source had been available, were simulated for the Reference and Forecast models validation. Source estimates for recent Chile 2010 tsunami, East Japan 2011, and Haida Gwaii, British Columbia 2012 tsunami were produced in NCTR, constrained with open-ocean tsunami records at DART stations. Source estimates for the Alaskan tsunami of 1964 and the Unimak 1946 tsunami were produced in NCTR, constrained with tide gage records. Author of the Alaskan tsunami source is Dr. Liujuan (Rachel) Tang. Validity of the sources is confirmed by fair agreement of the simulation results with each tsunami wave height measurements at tide gages at multiple locations Pacific-wide (<http://nctr.pmel.noaa.gov/database-devel.html>).

Figures 18 - 22 display tsunami time histories at Sitka gage simulated with Reference (red, top) and Forecast (red, bottom) models, as well as the measurements (black). Comparisons in five events display consistent results: for the first 4-5 hours after tsunami arrival, the wave envelope is followed in wide range of frequencies when modeled with the Reference Model. The lower frequency component of the wave is reproduced closely when modeled with the Forecast Model.

4.2 Stability Testing

To test the Forecast and Reference models for stability and for mutual consistence, a number of artificial events, including a micro-tsunami, a Mw 7.5 tsunami, and twenty mega-tsunamis of Mw 9.3 were simulated for 24 h with the both Models. The event sources were selected to represent different locations around Pacific Rim and in immediate vicinity of Sitka Sound (event Mega 20). All synthetic events emulate subduction-type scenarios, which might or might not correspond to a known type of seismic activity in each source region. In particular, subduction-type plate motion has not been observed in the Fairweather fault system (Suleimani et al., 2013). Hence Mega 20 tsunami event is not consistent with the known tectonic regime in the area. It is used only to test

the model's correct operation in wide range of forcing, and should not be interpreted for the hazard assessment purposes. For the mega-events, the slip of 25 m was distributed evenly among the unit sources. Location of the events is shown in Figure 17. Synthetic scenarios are listed in Table 3. The model results are presented below.

Figures 23 - 26 show time histories at the tide gage location and at the virtual gage on Japonski island, computed with the Forecast Model. Seven events representing different subduction zones including the local event (mega events 3, 4, 7, 8, 9, 14 and 20) were also simulated with the Reference Model. The solutions by the Forecast Model and the Reference Model fairly agree with each other.

Figures 27 - 33 show maximal water elevation with respect to still sea level in grids B and C for the above seven mega events, the Forecast Model in comparison with the Reference Model. The results are fairly consistent between the two models, though the Reference model is likely to produce higher maximum wave amplitude in a channel separating Sitka town from Japonski island. At the same time, both models indicate similar inundated areas, with the Forecast Model often indicating more extensive inundation even with lower maximum wave height in the area. The reason for this seeming paradox can be found in comparisons of tsunami time histories computed with the two models (Figures 23 - 26). Higher maximum wave amplitude returned by the Reference Model is due to higher frequency wave component not present in the Forecast Model. Total amount of raised water moving onshore can be thought of as wave height multiplied by half of the wave length, which is roughly proportional to the wave period. Hence short waves add little to inundation. Thus the Forecast Model is expected to communicate inundation hazard correctly, though this model might underestimate maximum wave amplitude and associated currents in the open water. An area inundated in all seven events was a low-lying Indian River valley opening into Sitka harbor, depicted in Figure 34.

5 Summary and Conclusion

A tsunami forecast model was developed for the community of Sitka, Alaska. The developed model has been implemented into NOAA's Short-term Inundation Forecast of Tsunamis (SIFT) to provide real-time modeling forecasts of the tsunami wave characteristics, runup, and inundation along Sitka's coastline. Discussion of the details of each individual component of the forecast model, including the bathymetry and topography, the basic model setup, and the model parameters are provided in this report. The forecast model employs grids as fine as 90 m in resolution and can accomplish a 10-hr simulation after tsunami arrival in under 6 minutes of computation time. A reference model was developed using grids as fine as 20 m in resolution, to provide a reference for evaluation of forecast model results and performance.

Model validations have been carried out for the Sitka Forecast and Reference models using 5 historical tsunami events (listed in Table 2). For each event, the two model results were compared with observations recorded at the NOS tide station located in Sitka Harbor. The computed results for both the Forecast and Reference Sitka models showed good agreement with observations.

20 hypothetical Mw 9.3 mega events, including a near field event generating 7.8-m high runup, were also simulated to ensure model stability. All model validation and stability tests demonstrated that the Forecast and Reference tsunami models developed for Sitka, Alaska, are accurate, robust, and efficient for their implementation into both the short-term real-time tsunami forecast system and post-event tsunami inundation investigations.

The bathymetry and topography used in the development of this forecast model was based on a digital elevation model provided by the National Geophysical Data Center and the author considers

it to be an adequate representation of the local topography/bathymetry. As new digital elevation models become available, forecast models will be updated and report updates will be posted at http://nctr.pmel.noaa.gov/forecast_reports/.

C SIFT Testing

By Lindsey Wright and Elena Tolkova

C.1 PURPOSE

Forecast models are tested with synthetic tsunami events covering a range of tsunami source locations and magnitudes. Testing is also done with selected historical tsunami events when available.

The testing of a forecast model has three objectives. The first objective is to assure that the results obtained with the NOAA's tsunami forecast system software, which has been released to the Tsunami Warning Centers for operational use, are consistent with those obtained by the researcher during the development of the forecast model. The second objective is to test the forecast model for consistency, accuracy, time efficiency, and quality of results over a range of possible tsunami locations and magnitudes. The third objective is to identify bugs and issues in need of resolution by the researcher who developed the Forecast Model or by the forecast system software development team before the next version release to NOAA's two Tsunami Warning Centers.

Local hardware and software applications, and tools familiar to the researcher(s), are used to run the Method of Splitting Tsunamis (MOST) model during the forecast model development. The test results presented in this report lend confidence that the model performs as developed and produces the same results when initiated within the forecast system application in an operational setting as those produced by the researcher during the forecast model development. The test results assure those who rely on the Sitka tsunami forecast model that consistent results are produced irrespective of system.

C.2 TESTING PROCEDURE

The general procedure for forecast model testing is to run a set of synthetic tsunami scenarios and a selected set of historical tsunami events through the forecast system application and compare the results with those obtained by the researcher during the forecast model development and presented in the Tsunami Forecast Model Report. Specific steps taken to test the model include:

- Identification of testing scenarios, including the standard set of synthetic events, appropriate historical events, and customized synthetic scenarios that may have been used by the researcher(s) in developing the forecast model.
- Creation of new events to represent customized synthetic scenarios used by the researcher(s) in developing the forecast model, if any.
- Submission of test model runs with the forecast system, and export of the results from A, B, and C grids, along with time series.
- Recording applicable metadata, including the specific forecast system version used for testing.
- Examination of forecast model results for instabilities in both time series and plot results.
- Comparison of forecast model results obtained through the forecast system with those obtained during the forecast model development.

- Summarization of results with specific mention of quality, consistency, and time efficiency.
- Reporting of issues identified to modeler and forecast system software development team.
- Retesting the forecast models in the forecast system when reported issues have been addressed or explained.

Synthetic model runs were tested on a DELL PowerEdge R510 computer equipped with two Xeon E5670 processors at 2.93 Ghz, each with 12 MBytes of cache and 32GB memory. The processors are hex core and support hyperthreading, resulting in the computer performing as a 24 processor core machine. Additionally, the testing computer supports 10 Gigabit Ethernet for fast network connections. This computer configuration is similar or the same as the configurations of the computers installed at the Tsunami Warning Centers so the compute times should only vary slightly.

C.3 Results

The Sitka forecast model was tested with SIFT version 3.2.

The Sitka, Alaska forecast model was tested with four synthetic scenarios and one historical event. Test results from the forecast system and comparisons with the results obtained during the forecast model development are shown numerically in Table 1 and graphically in Figures 44 to 48. The results show that the minimum and maximum amplitudes and time series obtained from the forecast system agree with those obtained during the forecast model development, and that the forecast model is stable and robust, with consistent and high quality results across geographically distributed tsunami sources. The model run time (wall clock time) was 4.5 minutes for 9.99 hours of simulation time, and 1.8 minutes for 4.0 hours. This run time is well within the 10 minute run time for 4 hours of simulation time.

A suite of four synthetic events was run on the Sitka forecast model. The modeled scenarios were stable for all cases run. Wave heights were less than 100 centimeters (cm) for all source zones tested. The largest modeled height was 97 cm from the Aleutian-Alaska-Cascadia (ACSZ 56-65) source zone. The smallest signal of 64 cm was recorded at the far field Central and South America (CSSZ 89-98) source. The comparisons between the development cases (shown in figures 21, 23, 24 of the model report) and the forecast system output were consistent in shape and amplitude for both the Tohoku 2011 historical event and tested synthetic events. The Sitka reference point used for the forecast model development is the same as what is deployed in the forecast system, so the results can be considered valid for the cases studied.

Scenario Name	Source Zone	Tsunami Source	α (m)	SIFT Max (cm)	Development Max (cm)	SIFT Min (cm)	Development Min (cm)
KISZ 22-31	Kamchatka-Yap-Mariana-Izu-Bonin	A22-31, B22-31	25	69.8	69.5	-83.7	-84.0
ACSZ 56-65	Aleutian-Alaska-Cascadia	A56-65, B56-65	25	97.1	98.7	-109.0	-109.9
CSSZ 89-98	Central and South America	A89-98, B89-98	25	64.0	64.1	-63.7	-63.6
NTSZ 30-39	New Zealand-Kermadec-Tonga	A30-39, B30-39	25	69.2	70.2	-99.9	-100.4
Tohoku 2011*	Kamchatka-Yap-Mariana-Izu-Bonin			26.6	32.1	-36.1	-27.5
